8 **Abstract** Over the past two decades, the interest to  
9 decrease the emission levels of greenhouse gases  
10 (GHGs) has increased. The livestock sector has been  
11 put under continuous supervision and regulation  
12 because it is an important source of GHG emissions.  
13 In 2012, it was estimated that 3.46 Gton CO<sub>2</sub>-eq was  
14 released from this sector, methane (CH<sub>4</sub>) being the gas  
15 with the highest contribution (43 %), followed by  
16 nitrous oxide (21 %). In order to determine real  
17 emissions, it is necessary to use precise and repro-  
18 ducible measuring methods which can be complex and  
19 expensive. The challenges in these methods are  
20 focused on achieving an accurate assessment and

monitoring of gas emissions, developing monitoring 21  
systems for the continuous measurement and imple- 22  
mentation of methodologies for their validation in 23  
field in order to understand the complex nature of 24  
environmental variables affecting gas production. 25  
Different techniques for the measurement of CH<sub>4</sub> 26  
and nitrous oxide (N<sub>2</sub>O) emissions are reviewed and 27  
discussed in this research. The passive flux sampling 28  
to measure emissions of these GHGs has been 29  
identified as an interesting alternative technique 30  
because it is practical, low cost and robust. This kind 31  
of sampler is highly adequate to measure emissions of 32  
N<sub>2</sub>O and CH<sub>4</sub> originating from some sources of the 33  
livestock sector, but at this moment, no prototypes are 34  
commercially available and thus more research is 35  
necessary in this field. 36

oxide · Passive flux sampler 39

1 **Introduction** 40

Livestock sector is growing at a faster pace. Total meat 41  
and milk production around the world increased from 42  
256 to 310 million tons and from 651 to 747 million 43  
tons, respectively during 2005–2013 (FAOSTAT 44  
2015). This faster growth has been associated with 45  
the increase of population and with the shifts in 46

47 consumption patterns (Van Beek et al. 2010). Thus,  
 48 livestock sector has been considered as an opportunity  
 49 for economic growth and poverty reduction in rural  
 50 areas (Stubbs 2010). However, livestock sector also  
 51 generates environmental impacts, such as: land degra-  
 52 dation, loss of biodiversity, spread of infectious  
 53 diseases, and pollution from effluents and GHG  
 54 emissions.

55 Livestock sector is the main source of GHG  
 56 emissions from agriculture; in 2012, this sector  
 57 contributed 65 % of total agricultural GHGs emis-  
 58 sions. Enteric fermentation and manure left on pasture  
 59 from grazing livestock are important emission  
 60 sources, representing 38.6 and 15.4 % of the total  
 61 agricultural emissions, respectively (FAOSTAT  
 62 2014). The manure management, and the manure  
 63 applied to soils are also sources of GHGs emissions,  
 64 representing 6.8 and 3.5 %, respectively.

65 The main source of CH<sub>4</sub> emissions is the enteric  
 66 fermentation and CH<sub>4</sub> is released through ruminant  
 67 eructation (Murray et al. 1999; Crutzen et al. 2006),  
 68 whilst N<sub>2</sub>O is mainly produced and released during  
 69 nitrification and denitrification process from NH<sub>3</sub>  
 70 present in urine and feces (Monteny et al. 2006;  
 71 Solomon 2007). Non-dairy cattle contribute 41 % of  
 72 total GHGs emissions from livestock sector, followed  
 73 by production of cattle dairy (20 %), buffaloes (9 %),  
 74 sheep and goats (6.5 %). The production from other  
 75 non-ruminant species, such as pigs and poultry  
 76 contribute 9 and 8 %, respectively (Gerber et al.  
 77 2013; FAO 2014).

78 Livestock production systems vary significantly  
 79 around the world depending on cultural, socio-econ-  
 80 omic and environmental conditions. In general,  
 81 livestock production systems can be classified as;  
 82 grazing, confinement and mixed system. The main  
 83 differences between them are related to the housing  
 84 type, feeding operations and manure management. In  
 85 grazing systems, the animals are raised on extensive  
 86 dry land areas, such as savannas, grasslands, scrub-  
 87 lands and deserts or in deciduous and evergreen forests  
 88 areas. These systems exist in 25 % of global land area.  
 89 Major countries with most land area in grazing  
 90 systems comprise Australia, China, United States,  
 91 Brazil and Argentina (Asner et al. 2004; Rearte and  
 92 Pordomingo 2014). These systems are used to raise  
 93 cattle, buffaloes, sheep and goats. In these systems,  
 94 CH<sub>4</sub> and N<sub>2</sub>O emissions are released directly to the  
 95 atmosphere as animals are raised in outdoor conditions

and their excreta is immediately deposited on the  
 grassland (Asner et al. 2004).

In confined animal farming operations, the animals  
 are fattened intensively with concentrated feed, com-  
 plemented with fodder, and crops, such as soybean and  
 corn (Hafla et al. 2013). In these systems, the  
 temperature, air circulation and waste disposal can  
 be controlled. There are separate buildings for non-  
 cattle and cattle production. The non-cattle buildings  
 are mechanically ventilated, such as buildings used to  
 raise pigs and poultry. The buildings for cattle  
 production are naturally ventilated or with a combined  
 system normally referred to as hybrid ventilation  
 (Arogo et al. 2003; Godbout et al. 2012). GHGs  
 emissions from confined system are released to the  
 atmosphere in the air flux exiting the system. These  
 systems are mainly distributed in the East and  
 Southeast Asia, Europe and North America, Southern  
 Brazil and some regions of Mexico, Colombia,  
 Venezuela, Nigeria, and Australia.

The mixed systems are commonly used to raise  
 ruminants around the world in intensive and extensive  
 mode producing about 75 % of milk and 60 % of meat  
 from ruminants around the world (Herrero et al. 2010).  
 These systems are characterized by integration of  
 livestock and arable crop production. The animals are  
 maintained in farms near land crops, where they are  
 fed mostly on grass and non-food biomasses obtained  
 from maize, millet, rice, and sorghum crops, and  
 manure is used as organic fertilizer on land crops.  
 Arogo et al. (2003) has estimated that 64 % of global  
 CH<sub>4</sub> emissions from enteric fermentation are issued  
 from mixed systems, whereas grazing systems gener-  
 ate 34 %.

## 2 Basic principle on the measurement of GHGs emissions

As emissions represent mass of a gas released by a  
 source per unit of time, the measurement of GHGs  
 emission generally requires techniques and instru-  
 ments to measure the concentration of gas (s) target;  
 and the air exchange rate or the vertical and horizontal  
 flux from a specific area. The measurement of gas  
 concentration can be done by direct detection in situ  
 using sensors or gas analyzer or by applying tech-  
 niques of sampling for after to measure gas concen-  
 tration in laboratory or in mobile unites installed in

142 field. In next sessions a brief description of current  
 143 techniques to measure gas concentration and air  
 144 velocity is done. After the measurement of gas  
 145 concentration and air flux, specific equations are used  
 146 to quantify GHGs emissions depending with the  
 147 A03 strategy and techniques selected. The Table 1  
 148 describes some equations reported for the estimation  
 149 of GHGs emission (Peu et al. 1999; Laguë et al. 2005;  
 150 Zhang et al. 2005; Sneath et al. 2006; Amon et al.  
 151 2007; Ngwabie et al. 2009; Wu et al. 2012; Zhu et al.  
 152 2014).

## 153 2.1 Techniques to measure gas concentration

### 154 2.1.1 Direct detection by using sensors and analyzers

155 Electrochemical, amperometric, or electronic sensors  
 156 are commonly used for direct detection of gases.  
 157 However, specific sensors to measure CH<sub>4</sub> and N<sub>2</sub>O  
 158 emission have important limitations. In the case of  
 159 CH<sub>4</sub>, its inertness difficult electrochemical reactions  
 160 due to its high tolerance to oxidation at lower  
 161 temperatures. It has been found that the strong C-H  
 162 bond requires high temperatures of around 400 °C for  
 163 its detection (Kamieniak et al. 2015). For the detection  
 164 of N<sub>2</sub>O, some biosensors using denitrification-enzyme  
 165 nitrous-oxide reductase have been reported, but the  
 166 upper value of detection range is around 1 mM. This  
 167 sensitivity is unsuitable to measure N<sub>2</sub>O at atmo-  
 168 spheric concentration where a sensitivity in ppb is  
 169 necessary (Tsugawa et al. 2012). Thus, the use of  
 170 sensors for CH<sub>4</sub> and N<sub>2</sub>O has been so far limited.

171 On the other hand, open-path analyzers, such as the  
 172 LI-7500A and LI-7700 analyzer based on wavelength  
 173 modulation spectroscopy, have been reported for  
 174 direct detection of CH<sub>4</sub> concentrations with an appro-  
 175 priate resolution at 10 Hz for continuous measurement  
 176 in field. (Felber et al. 2015). Also, new fast response  
 177 analysers based on tunable diode laser (TDL) and  
 178 quantum cascade laser (QCL) has been developed for  
 179 N<sub>2</sub>O measurements under field conditions (Rannik  
 180 et al. 2015). A description on the basic work principle  
 181 and some specification of gas analyzers is given in  
 182 Sect. 2.1.4.

### 183 2.1.2 Active and passive sampling

184 When direct detection of GHGs is not possible, air  
 185 samples are collected by using active or passive

186 sampling for subsequent analysis in laboratory or in  
 187 mobile units to measure gas concentration (Viguria  
 188 et al. 2015). Different sampling strategies can be  
 189 applied to collect air samples by using automatic  
 190 sampling systems, glass tubes, gas sampling bags or  
 191 diffusive devices. As the quantity of material collected  
 192 with gas sampling devices is often small, sensitive  
 193 analytical methods are required to detect and measure  
 194 concentration of the gas in a short time after collection.  
 195 A limitation of the sampling is that the gases can react  
 196 with dust particles, moisture and other compounds. In  
 197 some case, the gas containers can alter the chemical  
 198 composition of the target gas and result in an  
 199 erroneous estimate of the concentration (Lodge Jr  
 200 1988). Active sampling generally requires pumps to  
 201 pull air towards a collecting device for direct or  
 202 indirect measuring. Active sampling has being used to  
 203 estimate CH<sub>4</sub> and N<sub>2</sub>O in different studies (Laguë et al.  
 204 2005; Zhang et al. 2005; Sneath et al. 2006; Amon  
 205 et al. 2007). Some considerations, when active sam-  
 206 pling is used should be taken into account. For  
 207 example, when automatic sampling units are used,  
 208 the tubes used to transport the sampler need to avoid  
 209 water condensation. The sampling frequency is  
 210 defined depending upon the variability of the gas  
 211 target and the required accuracy. It is considered that  
 212 long measurement time is required to reach a correct  
 213 estimation of gas emission, because there are signif-  
 214 icant variations in gas concentrations and air exchange  
 215 rates. Zhu et al. (2014), have proposed a methodology  
 216 for a minimum continuous sampling period of 3 days,  
 217 taking air samples during each hour to capture the  
 218 diurnal variations of CH<sub>4</sub> and N<sub>2</sub>O emission. Barton  
 219 et al. (2015), reported a wide range analysis of the  
 220 uncertainties produced in N<sub>2</sub>O emission estimation  
 221 when the sampling frequency is not correctly defined.  
 222 On the other hand, passive sampler or passive flux  
 223 samplers are considered an appropriate tool for longer  
 224 sampling periods. In the case of NH<sub>3</sub> emission, these  
 225 samplers has been widely used in agricultural sources  
 226 (Mosquera et al. 2003; Dore et al. 2004). However,  
 227 these devices have not been reported to sample CH<sub>4</sub>  
 228 and N<sub>2</sub>O emissions to date. Thus, although direct  
 229 detection using portable gas analyzer is an innovative  
 230 alternative to measure gas emission, it is important to  
 231 evaluate and report the costs for your application, the  
 232 lifetime of the analyzers and the feasibility to measure  
 233 CH<sub>4</sub> and N<sub>2</sub>O emissions at different points. Likewise,  
 234 sampling strategies need to be appropriately defined

**Table 1** Equations proposed to quantify GHGs emissions using different techniques of measuring

Dynamic chambers (Aneja et al. 2006)	$\frac{dC}{dt} = \left( \frac{q[C_{air}] + \frac{dA}{V} \right) - (C) \left( \frac{LA_w}{V} + \frac{q}{V} \right) - R$	<p><math>C</math> = concentration of gas inside the chamber (ppbV)  <math>C_{air}</math> = concentration of gas in carrier air (ppbV)  <math>q</math> = flow rate of compressed air through the chamber (L/min)  <math>V</math> = volume of the chamber (L)  <math>A</math> = emission surface area covered by chamber (m<sup>2</sup>)  <math>A_w</math> = inner surface area of the chamber of inner and upper wall surfaces (m<sup>2</sup>)  <math>t</math> = time (s)  <math>L</math> = total loss of gas in the chamber per unit area (m min<sup>-1</sup>) due to reaction with inner and upper walls of the chamber  <math>R</math> = gas phase reactions inside the chamber</p>
Static chambers (Misselbrook et al. 2005)	$F = (C_o - C_i) \frac{v}{t}$	<p><math>J</math> = emission flux per unit area (μg [gas] m<sup>-2</sup> s<sup>-1</sup>)  <math>C_o - C_i</math> = concentration outlet and inlet air (μg m<sup>-3</sup>)  <math>v</math> = the volume or air drawn through the tunnel in the sampling period (m<sup>3</sup>/s)  <math>t</math> = time (s)</p>
Tracer gas (Zhang et al. 2005)	$V \frac{dC}{dt} + Q \cdot C = Q \cdot C_e + F$	<p><math>V</math> = effective volume of the enclosure (m<sup>3</sup>)  <math>Q</math> = air volume flow rate through the enclosure (m<sup>3</sup>/s)  <math>C</math> = internal concentration of tracer gas at time (<math>t</math>)  <math>C_e</math> = concentration of tracer gas in the atmosphere  <math>F</math> = tracer injection flow rate (m/s)  <math>t</math> = time (s)</p>
Micrometeorological (Khan et al. 1997)	$F_v = \frac{1}{x} \sum_{z_o}^{z_p} u_z \cdot (C_{Lz} - C_{wz}) \cdot \Delta z$	<p><math>x</math> = distance the wind travels across the pond (m)  <math>u_z</math> = mean wind speed (ms<sup>-1</sup>) at height <math>z</math> (m)  <math>(C_{Lz} - C_{wz})</math> = windward (background) and leeward gas concentrations  <math>z_o</math> = roughness length (the height at which <math>u_{z_o} = 0</math>)  <math>z_p</math> = height at which the gas concentration, assumed not be affected by the pond (<math>z_p = 3.6</math> m)  <math>z</math> = height (m)</p>
Livestock buildings (Godbout et al. 2012)	$E_{GHG} = (C_{out} - C_{in}) \times \frac{Q}{N_a} \times \frac{P_{atm} - P_v}{287 \times T} \times \frac{M_{GHG}}{M_{air}} \times 525.6$	<p><math>E_{GHG}</math> = CO<sub>2</sub>, CH<sub>4</sub> or N<sub>2</sub>O emissions (g yr<sup>-1</sup> animal<sup>-1</sup>)  <math>C_{out}</math> = exhaust gas concentration from the animal space (ppmv)  <math>C_{in}</math> = income gas concentration from the animal space (ppmv)  <math>Q</math> = Average room air exchange rate (m<sup>3</sup> air min<sup>-1</sup>)  <math>N_a</math> = Number of animals in the room  <math>P_{atm} - P_v</math> = atmospheric pressure at sea level and the vapor pressure (Pa)  <math>T</math> = temperature (K)  <math>M_{GHG}</math> = characterize the molar masses of CO<sub>2</sub> (44 g mol<sup>-1</sup>), CH<sub>4</sub> (16 g mol<sup>-1</sup>), or N<sub>2</sub>O (44 g mol<sup>-1</sup>)  <math>M_{air}</math> = molar mass of air (29 g mol<sup>-1</sup>)  <math>287</math> = is the thermodynamic constant of air (J kg<sup>-1</sup> K<sup>-1</sup>)  <math>525.6</math> = conversion factor (mg min<sup>-1</sup> to g yr<sup>-1</sup>)</p>

235 and compared with direct detection or measurement to  
 236 estimate the uncertainty, representation and  
 237 feasibility.

### 238 2.1.3 Gas chromatography

239 As mentioned previously, the measurement of GHGs  
 240 emission requires instruments to measure gas concen-  
 241 tration. Gas chromatography with selective detectors,  
 242 Fourier transform infrared spectroscopy (FTIR) and  
 243 photoacoustic spectroscopy (PAS) are the techniques  
 244 usually reported. Gas chromatography with flame  
 245 ionization detector (FID) is the most common tech-  
 246 nique used to measure CH<sub>4</sub> concentrations at a  
 247 detection level of 0.01 ppmv for most of the time  
 248 depending on the equipment used (Zhou et al. 2003;  
 249 Zhu et al. 2014). In the case of N<sub>2</sub>O quantification, an  
 250 electron capture detector (ECD) is commonly used at a  
 251 detection level of 0.030 ppmv (Rapson and Dacres  
 252 2014). Gas chromatography requires carrier gases,  
 253 such as zero grade nitrogen. In some case, impurities  
 254 from these gases interfere with the detection of ECD  
 255 (Rapson and Dacres 2014).

256 To measure GHGs concentrations directly in the  
 257 field using GC, a mobile laboratory with temperature  
 258 control is necessary. The mobile laboratory is  
 259 equipped with GC analyzer, air pumps, and thermo-  
 260 couples to monitor the temperature in ducts, inside and  
 261 outside the laboratory. Gas chromatographic analysis  
 262 requires commonly 5 min and a turnover of less than  
 263 7 min between analyses. A data logger controlled by  
 264 the computer of the GC is used to acquire and archive  
 265 various parameters measured during periods of anal-  
 266 ysis (Godbout et al. 2012; Rapson and Dacres 2014).  
 267 Although, gas chromatography permits the measure-  
 268 ment of GHGs concentration in the field, the require-  
 269 ments limit its application to a small number of  
 270 sampling sites. However, when samples are collected  
 271 in field to analyze after in the laboratory; gas  
 272 chromatography permits the measurement of gas  
 273 samples from different sampling points. The analysis  
 274 of gas concentration in laboratory using gas chro-  
 275 matography is considered as an alternative strategy,  
 276 but not reports comparing the accuracy of sampling in  
 277 field and in the laboratory were identified during this  
 278 review.

### 2.1.4 Spectroscopic techniques

280 Spectroscopy is another technique used to measure gas  
 281 concentration; the concentration is determined by the  
 282 absorption of radiation when it is transmitted through  
 283 the air sampler. Infrared, photoacoustic and laser  
 284 spectroscopy have been used to measure CO<sub>2</sub>, N<sub>2</sub>O,  
 285 CH<sub>4</sub>, H<sub>2</sub>O and CO concentrations. Infrared spec-  
 286 troscopy (IR) is based on irradiation of a sample with  
 287 IR radiation source, which causes specific resonant  
 288 frequencies, depending upon the types of molecular  
 289 bonds present in the sample (Kamieniak et al. 2015).  
 290 IR uses closed or open path Fourier transform infrared  
 291 spectrometer (FTIR) to simultaneously measure the  
 292 concentration of different gases with a frequency of  
 293 few seconds or minutes (Järvi et al. 2009; Kroon et al.  
 294 2010; Detto et al. 2011; McDermitt et al. 2011; Rapson  
 295 and Dacres 2014). The spectral region used to measure  
 296 N<sub>2</sub>O and CH<sub>4</sub> is around 2188–2224 and  
 297 1500–7425 cm<sup>-1</sup>, respectively. The detection limit  
 298 depends on the sensitivity of the instrument used. For  
 299 example, Grutter (2003) reported a detection limit of  
 300 0.024 and 0.003 ppm for CH<sub>4</sub> and N<sub>2</sub>O, respectively;  
 301 while Ngwabie et al. (2009) reported 0.4 ppm for CH<sub>4</sub>  
 302 and 0.03 ppm for N<sub>2</sub>O. The main drawbacks of FTIR  
 303 and other spectroscopy techniques, such as laser  
 304 spectroscopy are higher cost and energy requirements.  
 305 Also, the overestimation or underestimation of gas  
 306 concentration caused by the interference of non-target  
 307 gases is other drawback. This interference is generated  
 308 by overlap spectra of several gases. For example, N<sub>2</sub>O  
 309 spectra can present interferences with CH<sub>4</sub>, H<sub>2</sub>O, CO<sub>2</sub>  
 310 and CO and generate relative errors of 0.1–3 %  
 311 (Grutter 2003). Currently, portable analyzers based  
 312 on infrared spectroscopy (FTIR) are being used to  
 313 direct detection on CH<sub>4</sub>. However, the use of these  
 314 analyzer types to detect N<sub>2</sub>O in field was no identified.  
 315 Laser spectroscopy is another technique to quantify  
 316 gas concentration. This technique is based on the use  
 317 of optical parametric oscillator or a quantum cascade  
 318 laser (QCL) as radiation source. These laser sources  
 319 emit light in the mid-IR range, where the molecules  
 320 have higher absorption coefficients. Laser spec-  
 321 troscopy is considered the more selective technique  
 322 for the identification of components from a gaseous  
 323 mixture, due to its high radiation, narrow line width  
 324 and high spectral resolution (Köhrling et al. 2015).

325 However, the application of this technique to measure  
 326 GHGs emissions in field is even limited. Recently, the  
 327 combination of laser and infrared spectroscopy was  
 328 reported by Tao et al. (2015). They developed an open-  
 329 path, multiple trace gas mobile by integrating indi-  
 330 vidual open-path analyzers to detect CO<sub>2</sub>, CH<sub>4</sub>, N<sub>2</sub>O,  
 331 H<sub>2</sub>O, NH<sub>3</sub> and CO simultaneously at 10 Hz. This  
 332 analyzer provides a lightweight, compact and low-  
 333 power alternative to the closed-path sensors. However,  
 334 they concluded that more experiments are needed to  
 335 verify the precision and calibration of this new  
 336 analyzer while driving, because the power consump-  
 337 tion is from a mobile platform. Also, the optimization  
 338 of the sampling strategy for mobile-based measure-  
 339 ments is necessary in order to quantify emissions  
 340 accurately.

341 Photoacoustic spectroscopy (PAS) is another tech-  
 342 nique used to quantify gas concentration. It is based on  
 343 the generation and detection of radiation and the  
 344 resonant absorption (Rocha et al. 2012). In this  
 345 technique, a quantum-cascade laser is used as light  
 346 source. The difference between PAS and laser spec-  
 347 troscopy is that the samples are exposed to a modu-  
 348 lated radiation and the acoustic waves resulting from  
 349 the absorption of laser radiation produce a sound  
 350 (photoacoustic effect) which is detected by highly  
 351 sensitive coupled microphones. These microphones  
 352 convert the sound signal into an electric signal, which  
 353 is filtered and detected by an amplifier. Photoacoustic  
 354 spectroscopy has been used to quantify the concen-  
 355 tration of several gases in a range of ppbv and sub-  
 356 ppbv. In the case of CH<sub>4</sub> and N<sub>2</sub>O, the detection limit  
 357 is around 30 and 7 ppb, respectively (Kang et al. 2014;  
 358 Rapson and Dacres 2014; Köhring et al. 2015). It can  
 359 be a limiting factor when higher sensitivity is required.  
 360 The main advantage of PAS detection is that can be  
 361 portable and to work at atmospheric pressure. PAS is  
 362 considered a cost efficiency technique with mobility  
 363 possibility for a continuous measurement (Kang et al.  
 364 2014). However in some case, PAS can overestimate  
 365 N<sub>2</sub>O fluxes by 13.6 % in relation to GC due to  
 366 humidity interference in CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O measure-  
 367 ments (Nicoloso et al. 2013).

368 Thus, there is a wide range of techniques to quantify  
 369 gas concentration, Kamieniak et al. (2015) and Rapson  
 370 and Dacres (2014) have reported a more detailed  
 371 description of analytical techniques to quantify CH<sub>4</sub>  
 372 and N<sub>2</sub>O emissions. However, to evaluate the appli-  
 373 cation of these techniques in real conditions, it is

necessary to have an exhaustive analysis to compare  
 the technical and economic requirements for a  
 continuous in situ measurement of GHGs emissions.  
 Also, the instrumental stability, random errors of  
 fluxes originate from the stochastic nature of turbu-  
 lence and correcting procedures that can systemati-  
 cally affect the accuracy of measured fluxes when  
 conducting long term measurements has been  
 suggested.

## 2.2 Techniques for measurement of air exchange rate and air flux

Air exchange rate or ventilation rate represents the  
 volume of air replaced in a specific space per unit of  
 time. It can be expressed as air exchange per minute  
 (ACM) or per hour (ACH). In animal houses, the air  
 exchange is necessary to maintain the health and  
 productivity of farm workers and animals. Hence, the  
 main objective of air exchange is to replace the stale  
 air with fresh air to maintain the indoor air quality  
 within the comfort zone of the animals. For example,  
 the ventilation rate recommended for cattle is around  
 100 m<sup>3</sup>/h per cow; while for pigs, it is around 60 m<sup>3</sup>/h  
 per pig. However, ventilation rate required for each  
 animal production system is dependent on seasonal  
 and environmental changes (Chastain 2000). The  
 ventilation rate must be estimated according to  
 emission rate of pathogen organisms, dust, CO<sub>2</sub> and  
 other gases, such as NH<sub>3</sub>, CH<sub>4</sub>, and N<sub>2</sub>O according to  
 animal heat production. A perfect mixing depends on  
 the ventilation system used to enable homogeneity of  
 air inside the building and also the animal distribution  
 inside the house. The ventilation conditions depend on  
 many parameters, such as seasonal environmental  
 variations, wind speed and direction, temperature,  
 animal heat production, building characteristics,  
 which vary in space and time.

Some techniques to measure ventilation rates  
 include: anemometers, tracer techniques; diffusion of  
 animal-produced CO<sub>2</sub> or heat. These techniques have  
 been widely described by different researchers (Van  
 Buggenhout et al. 2009). Tracer techniques and vane  
 and thermal anemometers have been mostly consid-  
 ered appropriate for the measurement of ventilation  
 rate in small buildings with mechanical ventilation and  
 single ventilation outlet. The accuracy of these  
 techniques in these systems has been reported to be

420 between 90 and 96 % (McWilliams 2002). However,  
 421 in large ventilated systems, it is difficult that the tracer  
 422 follows the same path that the gas of interest due to  
 423 incomplete mixing by differences among fans or  
 424 ventilation effectiveness (Scholtens et al. 2004; Khan  
 425 et al. 2008; Samer et al. 2014). This problem is more  
 426 evident in naturally ventilated buildings, because in  
 427 these systems, it is difficult to release the tracer gas  
 428 with the same dispersion properties as the target gas  
 429 over a large and open distance. Thus, when a perfect  
 430 mixing of air is not achieved, the results will not be  
 431 reliable (Van Buggenhout et al. 2009).

432 Van Buggenhout et al. (2009) reported a compar-  
 433 ison of techniques for measurement of ventilation rate  
 434 in naturally ventilated systems and they showed lack  
 435 of accuracy in all the techniques reviewed. The  
 436 accuracy reported was around 10–15 % using tracer  
 437 gases and 25 % for hot wire anemometers. These  
 438 results showed that the measurement of ventilation  
 439 rate in large buildings with natural ventilation has  
 440 significant influence on the measurement of GHGs  
 441 emissions. Since high amounts of GHGs are emitted  
 442 from mixed systems of animal production which  
 443 include open areas, it is necessary to develop and  
 444 evaluate new techniques to improve the estimation of  
 445 ventilation rate.

446 Ultrasonic anemometers are generally used to  
 447 measure air flux with higher frequency. These devices  
 448 measure wind velocity and temperature in three  
 449 coordinates. Anemometers are mounted on a horizon-  
 450 tal support on a tower. The air flux is estimated by  
 451 using dispersion models to describe the vertical  
 452 profiles. The main limitation of air flux measurements  
 453 is that the fluxes vary spatially, and differ from day-to-  
 454 day and within the day in response to multiple factors  
 455 that regulate production, consumption and emission  
 456 the GHGs (Zhu et al. 2014).

### 457 3 Techniques for measurement of GHGs emissions 458 in the field

459 Gas flux chamber, micrometeorological and tracer  
 460 gases at animal scale are the techniques more studied  
 461 for measurement of GHGs emissions from livestock  
 462 sources. Although these techniques have been widely  
 463 described in diverse reviews (Storm et al. 2012;  
 464 Hensen et al. 2013; Fonollosa et al. 2014), the main  
 465 objective of the present review is to compare results

from the evaluation of these techniques in the field 466  
 describing briefly each one. 467

#### 3.1 Gas flux chamber 468

This technique consists of obtaining a representative 469  
 sample from emitting source enclosed in a static or 470  
 dynamic chamber in order to perform mass balances. 471  
 In dynamic chambers, controlled air is blown through 472  
 the chamber and air samples are collected at the inlet 473  
 and outlet. These chambers are generally used to 474  
 measure GHGs emissions from liquid surfaces and 475  
 CH<sub>4</sub> from individual or small groups of ruminants to 476  
 compare gas emissions from feeding diets and to 477  
 evaluate the use of additives for mitigation of CH<sub>4</sub> 478  
 production in the rumen (Lagué et al. 2005; Sneath 479  
 et al. 2006; Storm et al. 2012). When dynamic 480  
 chambers are used to measure CH<sub>4</sub> emissions from a 481  
 sample of animals, an accuracy of around 95 % can be 482  
 achieved. However, when these results are extrap- 483  
 olated to estimate CH<sub>4</sub> emissions from a herd, important 484  
 uncertainty can be obtained. The overestimation has 485  
 been associated with the variability of air distribution 486  
 in the chamber during the test; difference among 487  
 animals evaluated and the animals comprising the herd 488  
 due to genetic characteristics and growth stage; 489  
 differences among types of pasture or crops used to 490  
 feed to the animals during the measuring and the 491  
 consumed during the grazing. Currently, new chamber 492  
 systems have been developed to improve the air 493  
 exchange rate in the chamber by integration of a series 494  
 of ventilated hood chambers; a fresh air supply and a 495  
 system to deliver the air in a metered ventilation (Maia 496  
 et al. 2015). However, the cost of the measuring 497  
 system and the data extrapolation was not discussed. 498  
 In other studies, models, such as Nordic dairy cow 499  
 model Karoline was used to predict CH<sub>4</sub> emissions. 500  
 This model describes the digestion and metabolism of 501  
 nutrients. The model integrate the typical range of 502  
 diets fed to dairy cattle (Ramin and Huhtanen 2015). 503  
 The model evaluation using observed data from 504  
 studies reporting CH<sub>4</sub> emissions from respiration 505  
 chamber showed a good relationship between pre- 506  
 dicted and observed CH<sub>4</sub> emissions with a small root 507  
 mean square error of prediction ( $R^2 = 0.93$ ). Thus, 508  
 these new developments from the use of active 509  
 chambers and modelling can be an alternative to 510  
 estimate CH<sub>4</sub> emissions with more accuracy. How- 511  
 ever, an analysis on the cost to adapt these systems at 512

513 different sampling points will be necessary. Also, it is  
514 important to consider that the estimation of GHGs  
515 should integrate the seasonal and time variations.

516 On the other hand, static chambers are generally  
517 used to measure N<sub>2</sub>O from agricultural soil surfaces  
518 after manure application. In these chambers, no air is  
519 blown through the chamber and the variation of  
520 concentration is measured over time (Rochette and  
521 Eriksen-Hamel 2008). Static chambers are considered  
522 relatively inexpensive, versatile for field application  
523 and easy to deploy. However, uncertainties of N<sub>2</sub>O  
524 emissions around 17–20 % have been reported and  
525 associated with the respiratory activity of plants or  
526 microorganisms that absorb or release gases during the  
527 measurement of emissions. Also, the insertion and  
528 removal of chambers during the sampling can cause  
529 disruption and gas flux alteration (Rochette and  
530 Eriksen-Hamel 2008; Parkin et al. 2012). An inade-  
531 quate mixing of the headspace air, pressure changes,  
532 and increase in headspace gas concentration can  
533 affected the estimation of GHGs emission when static  
534 chambers are used (Zhu et al. 2014). Some modifica-  
535 tions in chamber characteristics and operation were  
536 proposed by Parkin et al. (2012). They reported that  
537 the flux detection limit of the chamber systems  
538 depends on several factors, such as the type of the  
539 chamber and respective sampling method, the preci-  
540 sion of the instrument, chamber dimensions and  
541 operation time. They proposed a model to scale up  
542 their results, but their study only considered sampling  
543 and analytical precision associated with trace gas  
544 concentration measurement. However, it is necessary  
545 to evaluate other sources of variability, such as  
546 chamber leakage and changes in biological activity  
547 during the chamber deployment period.

### 548 3.2 Tracers gases technique to measure CH<sub>4</sub> 549 emissions from animal scale

550 Other application of tracer gases is related to the  
551 estimation of CH<sub>4</sub> emissions from enteric fermenta-  
552 tion of ruminant animals by using SF<sub>6</sub> as tracer gas. In  
553 this technique, SF<sub>6</sub> is continuously released from a  
554 permeation tube inserted in the rumen of the animal.  
555 The gas ratio of SF<sub>6</sub>:CH<sub>4</sub> is determined over a 24 h  
556 period by analysis of the exhaled gases and collected  
557 on a PVC canister which is placed around the nose and  
558 mouth. The rate at which the gas is released from the  
559 permeation tubes is measured a priori in the laboratory

(Storm et al. 2012). Some limitations associated with  
the estimation of CH<sub>4</sub> using tracer techniques are:  
interferences of canister with grazing, overestimation  
of feed dry matter intake (DMI), labour intensive due  
to animal handling, sampling tube obstructions, broken  
collection tubes and unsuitability of capillary  
tubes to continuously collect gas at a constant rate for  
24 h (Hammond et al. 2015).

A system to measure CH<sub>4</sub> emissions by using  
propane as gas tracer technique combined with a  
dynamic chamber including systems for animal radio-  
frequency identification, baiting and a measurement  
was reported by Hristov et al. (2015). This technique is  
known as automated head-chamber system (AHCS). It  
is based on periodic attraction of animals to a AHCS  
unit placed in a grazing system. When the animals are  
attracted to AHCS, a fan pulls air over its head to  
collect CH<sub>4</sub> and CO<sub>2</sub> into an air intake manifold. The  
air flow velocity is measured with a hot-film  
anemometer. A continuous subsample of air is then  
extracted and routed into a secondary sample filter to  
analyze gas concentration using two non-dispersive  
infrared analyzers. AHCS also includes additional  
sensors to measure air temperature, and humidity; bait  
drop, atmospheric pressure, flow rate of the gas tracer,  
and head position. The main advantage of AHCS over  
respiration chambers is that the natural environment of  
animals is not restricted. The authors considered that  
this system is less expensive than a traditional  
respiration chamber and much simpler to operate  
compared with SF<sub>6</sub> tracer method. However, the data  
registered to estimate CH<sub>4</sub> emissions is dependent on  
the number of animals attracted to AHCS and hence it  
could not be representative.

### 3.3 Micrometeorological techniques

Different micrometeorological techniques have been  
reported for the measurement of GHGs emissions  
from housing or feedlot facilities, manure storage and  
manure applications on soil (Harper et al. 2011;  
McGinn 2013). These techniques are based on the use  
of meteorological sensors and gas analyzers of higher  
frequency to follow simultaneous and contiguous  
fluctuations of emissions (Storm et al. 2012; Vergé  
et al. 2012; Hensen et al. 2013). Emissions are  
calculated by measuring the horizontal or vertical  
concentration and meteorological data, such as wind  
speed, wet and dry-bulb air temperatures, net

radiation, and heat fluxes. To measure gas concentration, these techniques use laser and infrared spectroscopy analyzers or gas sampling techniques (Hensen et al. 2013; Fonollosa et al. 2014; Laville et al. 2015; Viguria et al. 2015).

Micrometeorological techniques include flux gradient (Köhring et al. 2015), eddy covariance (EC), relaxed eddy accumulation (REA), integrated horizontal flux (IHF), boundary-layer budgeting (BLB), vertical radial plume mapping (VRPM) and inverse dispersion analysis using models, such as backward Lagrangian stochastic (bLS) model (Harper et al. 2011; Fonollosa et al. 2014; Rapson and Dacres 2014; Laville et al. 2015). The differences among micrometeorological techniques are related with the type of analyzer used to determine concentrations, sampling location, and geometric configuration of the emission source, wind conditions and the process used to calculate the emission flux. For example, VRPM technique uses an open path optical analyzer to estimate the horizontal flux of gas emissions passing from the downwind emission source, whilst bLS technique calculates the emissions from distributed sources with a backward Lagrangian Stochastic dispersion model measuring the gas concentration in downwind or even over the source using only a single analyzer (Khan et al. 1997; Anderson et al. 2004; Kroon et al. 2007; Mammarella et al. 2010; Ro et al. 2011; McGinn 2013; Fonollosa et al. 2014; Rapson and Dacres 2014). Although these techniques have been suggested for grazing and mixed production systems, the emission values can result in an overestimation of up to 10–27 % in comparison with the gas tracer technique using SF<sub>6</sub> (Grainger et al. 2007). The principal limitation of micrometeorological techniques is that they are dependent on simplifying assumptions regarding uniformity and homogeneity of airflow which is difficult to reach under real conditions. Also, the required equipment is often costly (Bonifacio et al. 2015).

Table 2 shows results of CH<sub>4</sub> and N<sub>2</sub>O emissions from different sources, using the techniques described earlier. It can be seen that for open sources such as feedlot, grazing cattle or buildings with mechanical ventilation, micrometeorological techniques have been used. In the case of slurry storage, a dynamic chamber is the common technique used to quantify GHGs emissions (Husted 1993; Peu et al. 1999; Laguë et al. 2005; Sneath et al. 2006; Amon et al. 2007).

Also, it can see that the values of CH<sub>4</sub> and N<sub>2</sub>O emissions dependent on many factors such as environmental conditions, type of production system, type of emission source, physical and chemical characteristics of the emission source, manure management processes, ventilation type if it is in the animal house, measuring method selected and the combination of techniques used to measure gas concentration and air flux; the strategies applied to analyse the sample, type and time of sampling, characteristic of the farm, year season. Thus, the estimation of GHGs from livestock sector faces challenges to cover in next years.

#### 4 Challenges and perspective to measure nitrous oxide and methane emissions from livestock sector

- The trends on consumption and production of livestock products allow visualizing the problematic to face the target to decrease GHGs emissions. Livestock sector integrates a wide variety of production models around the world with specific characteristics that require particular strategies to measure GHGs emissions. Since these production models are dependent on cultural, socio-economic and environmental conditions, substantial seasonal and spatial variability in GHGs emissions among sites have been identified. Thus, to achieve an accurate assessment and monitoring of gas emissions represents a big challenge; because livestock sector requires continuous measurement and a higher number of sampling sites which implies higher cost.
- Unlike in other sectors involving GHGs emissions, in livestock sector, the strategy to establish mechanism of control and measuring of GHGs emissions is not clear. This situation makes it difficult to define an appropriate cost and complexity in the strategies and methods required for a correct estimation of CH<sub>4</sub> and N<sub>2</sub>O in livestock sources. As the grade of complexity and cost of a method of measurement is relative to who adopts the approach. Thus, it is necessary to define criteria to establish user type, cost, technology degree and complexity of the methods required to measure GHGs emission in real conditions.

**Table 2** Nitrous oxide and methane emissions from livestock sources using different measurement techniques

Emission source	CH <sub>4</sub> emission	N <sub>2</sub> O emission	Technique used to quantify emission	Technique used to measure concentration/and flux	References
Feedlot with dairy cattle	16.88 g/kg of milk 397 g/cow day 279 g/heifer day	1.68 g N <sub>2</sub> O/kg of milk 35.7 g/cow day 24.2 g/heifer day	Micrometeorological	Active sampling and laboratory analysis/ Anemometer and backward Lagrangian stochastic inverse- dispersion technique	(Zhu et al. 2014)
Naturally ventilated dairy cattle building	200–400 g/HPU* day	<4 g/HPU day	Tracer gas-multipoint sampling	Multiplexer gas monitor in situ-GC/SF <sub>6</sub> as gas tracer	(Zhang et al. 2005)
Naturally ventilated dairy cattle building	290–230 g/HPU day	Low emissions into the building	Tracer gas-multipoint sampling	Photoacoustic spectroscopy/ultrasonic anemometers	(Wu et al. 2012)
Naturally ventilated dairy cattle building	8–11.2 g/HPU day	Low emissions into the building	Tracer gas-multipoint sampling	Photoacoustic multi-gas analyzer/ ultrasonic anemometers	(Ngwabie et al. 2009)
Ventilated housing for fattening pigs (with manure removal)	1.48 g/pig place day	0.070 g/pig place day	Micrometeorological	FTIR spectroscopy-analysis in situ/ ultrasonic anemometers	(Amon et al. 2007)
Ventilated housing for fattening pigs (without manure removal)	3.4 g/pig place day	0.11 g/pig place day	Micrometeorological	FTIR spectroscopy-analysis in situ/ ultrasonic anemometers	(Amon et al. 2007)
Liquid animal slurries	Not reported	1.90–5.98 g/m <sup>2</sup> day	Dynamic chamber	Active sampling-GC and infrared spectrophotometer/flow meter	(Peu et al. 1999)
Liquid pig manure	3.75 g CO <sub>2</sub> equivalent/kg day	<0.01 g CO <sub>2</sub> equivalent/kg day	Dynamic chamber	Active sampling in field GC/flow meter	(Laguë et al. 2005)
Pig slurries (warm-50 days)	5 g/m <sup>3</sup> day	0.46 g/m <sup>3</sup> day	Dynamic chamber	FTIR spectroscopy-analysis in situ/flow meter	(Amon et al. 2007)
Pig slurries (cold-50 days)	3.2 g/m <sup>3</sup> day	0.72 g/m <sup>3</sup> day	Dynamic chamber	FTIR spectroscopy-analysis in situ/flow meter	(Amon et al. 2007)
Slurry storage	35.26 g C/m <sup>3</sup> day	≈0	Tracer gas-multipoint sampling	Multiplexer gas monitor-GC/SF <sub>6</sub> as gas tracer	(Sneath et al. 2006)
Pig solid manure (summer-31 days)	17.9–92 g/m <sup>3</sup> day	Not reported	Dynamic chamber	Active sampling and laboratory analysis/ Anemometer and backward Lagrangian stochastic inverse- dispersion technique	(Zhu et al. 2014)

\* HPU = 1000 W of total heat produced by the livestock at an environmental temperature of 20 °C. Some values were modified for the standardization of the units of measuring and can differ of the values reported in the original source

701 • Special attention should be given to non-dairy and  
702 dairy cattle production, as it contributes about two-  
703 thirds of total GHGs emissions from livestock

sector. Mixed and grazing systems are commonly  
used for their production. In these systems, it is  
difficult to measure GHGs emissions as they

707 include open areas where air flow cannot be  
708 measured accurately. In the case of confinement  
709 systems, to produce ruminants and non-ruminants,  
710 tracer techniques and strategies of sampling to  
711 measure gas concentration could be the most  
712 appropriate technique to measure GHGs emis-  
713 sions. However, due to the fact that the measure-  
714 ment of GHGs emissions requires equipment to  
715 measure gas concentration and air flow rate, the  
716 cost and requirements for the continual measure-  
717 ment in the field remains a challenge as the  
718 available techniques are considered complex and  
719 expensive. Thus, new methods, techniques and  
720 instruments are necessary to measure simultaneous  
721 and continuously the emissions from livestock  
722 sector.

- 723 • It is necessary to develop reference methods for the  
724 comparison of available and new techniques  
725 developed for the measurement of CH<sub>4</sub> and N<sub>2</sub>O  
726 emissions from different livestock sources, as  
727 while considering the multiple alternatives to  
728 measure gas concentration, air flux, detection or  
729 sampling strategies, there are many combinations  
730 to quantify GHGs emissions.
- 731 • Passive flux sampling is considered a robust  
732 technique with lower level of operational require-  
733 ments and capital investment to set up a measure-  
734 ment in agricultural sources to measure NH<sub>3</sub>  
735 emissions from soil, manure management and  
736 buildings with mechanical ventilation. However,  
737 until date, its application to measure GHGs  
738 emissions is not reported. Thus, it could be put in  
739 perspective to evaluate the feasibility of this  
740 technique to quantify GHGs emissions from some  
741 livestock sources.

742 **Acknowledgments** Our sincere thanks go to Agriculture and  
743 Agri-Food Canada for the economic support by means of the  
744 Agricultural Greenhouse Gases Program (AGGP), and INRS-  
745 ETE to the Instituto Tecnológico Superior de Perote (ITSPe) for  
746 the support and collaboration in the research stage of main  
747 author, and to the Program for the Professional development of  
748 Professors (Prodep-Mexico) for the grant that let to perform this  
749 research stage.

## Author Query Form

**Please ensure you fill out your response to the queries raised below and return this form along with your corrections**

Dear Author

During the process of typesetting your article, the following queries have arisen. Please check your typeset proof carefully against the queries listed below and mark the necessary changes either directly on the proof/online grid or in the 'Author's response' area provided below

Query	Details Required	Author's Response
AQ1	Please check and confirm the affiliations have been correctly identified and amend if necessary.	
AQ2	Please check and confirm the city name for affiliation 4.	
AQ3	References Aneja et al. (2006), Misselbrook et al (2005) are cited in text but not provided in the reference list. Please provide references in the list or delete these citations.	
AQ4	We have changed the following author name Rapsen to Rapson in reference list and citation. please check and confirm.	
AQ5	Please provide the complete details of the references Barton et al (2015), Herrero et al (2010), Mosquera et al (2003).	
AQ6	Please check and confirm the publisher location of the references Godbout et al (2012), McWilliams (2002), Zhou et al (2003).
